Interactive Discussion

Abstract

An increasing trend in global streamflow has been variously attributed to climate change, land use, and a reduction in plant transpiration under higher CO₂ levels. To separate these influences, we use a subset of ~1000 United States Geological Survey stream gauges primarily from small, minimally disturbed watersheds to estimate annual streamflow per unit area since 1920 on a uniform grid over the coterminous United States. We find that although streamflow has indeed increased over this period taken as a whole, this increase has not been uniform in time but concentrated in the late 1960s, when precipitation increased. Since the early 1990s, both precipitation and streamflow show nonsignificant declining trends. Multiple regression of streamflow against precipitation, temperature and CO₂ suggests that higher CO₂ levels may increase streamflow, presumably due to the physiological plant response to CO₂, but that this positive response is more than offset by the concomitant increasing evaporation due to global warming, so that the net impact of greenhouse gas emissions has been to increase evaporation and reduce streamflow. The suppression of plant transpiration through higher CO₂ levels seems to be particularly important for sustaining high streamflow in recent decades in the Great Plains, where precipitation is concentrated during the growing season.

1 Introduction

Streamflow is important in its own right, as sustaining aquatic life and human water uses, and as a component of the terrestrial water budget. Not surprisingly, several attempts have been made to look in streamflow records for the impact of global warming, other climate variability, and nonclimatic human disturbance, often with an eye to testing models used to predict future changes in the water cycle. Probst and Tardy (1987, 1989) examine discharge records of 50 large rivers, filling in gaps in the records through linear correlation with measured precipitation. They find increasing streamflow

over 1910–1975 in Africa and the Americas, decreasing streamflow in Europe and Asia, and worldwide a linear trend corresponding to a 3% increase over that period, which they correlate with warming. [Labat et al. \(2004\)](#) analyze runoff records for 221 large rivers, estimating missing values using wavelet transforms. For the periods 1900–1975 (corresponding to [Probst and Tardy's](#) end year) and 1925–1994, they find increasing streamflow in Africa, the Americas, and Asia and decreasing streamflow only in Europe, for a global increase of 3% over 1900–1975 and 8% over 1925–1994, which they propose is evidence for acceleration of the hydrologic cycle caused by global warming; linear regression of runoff on annual global temperature gives a 4% increase per K warming.

[Gedney et al. \(2006\)](#) use a land surface model driven by observed climate in an attempt to more rigorously determine the causes for the increased streamflow noted by Labat et al. They find that observed climate changes are insufficient to explain the streamflow increase while changes in land use are modeled to have negligible impact on continental or global streamflow. The observed trend can be matched only by including the effect of higher CO₂ levels in suppressing plant transpiration and thus increasing the share of precipitation that runs off rather than evaporates. Extending this effect into the future, [Betts et al. \(2007\)](#) find that including the favorable impact of high CO₂ on streamflow increases projected global streamflow by an amount comparable to that expected from the climate-induced acceleration of the hydrologic cycle. By contrast, [Piao et al. \(2007\)](#), simulating 20th century trends in runoff using a different land surface model, find that suppression of transpiration is not necessary to explain the increase found by [Labat et al.](#); in their model, transpiration is not suppressed by higher CO₂ levels because the increased water use efficiency is offset by faster plant growth and more leaf area. Instead, they find that land use change, specifically deforestation, can explain much of the observed increase in runoff.

Several studies have examined trends in streamflow in the United States (US), using observations from parts of the extensive United States Geological Survey (USGS) stream gauge network, usually streams from the Hydroclimatic Data Network (HCDN),

a subset of USGS stream gauges chosen for their long continuous records and minimal disturbance of flow due to human land use or water diversions over their periods of measurement (Slack and Landwehr, 1992). Lettenmaier et al. (1994) examine trends in monthly streamflow, as well as temperature and precipitation, for 1948–1988, finding large increases in cold-season streamflow in the Northeast and Midwest over that period. Lins and Slack (1999) focus on streams with multidecade records that extend through 1993 and find that many streams have shown significantly larger low and medium flows, while high flows do not increase as much. McCabe and Wolock (2002), focusing on the period 1941–1999, find the same pattern of increasing minimum and median annual flow, but point out that the increase took place abruptly around 1970, coincident with an increase in recorded precipitation, and that therefore the increasing trend cannot be confidently extrapolated into the future.

In the work presented here, our aims were (1) to use available streamflow observations to map annual streamflow departures for the coterminous US for as long a period as possible; (2) to evaluate trends in annual streamflow over the coterminous US; and (3) to correlate deduced changes in streamflow with climate variables and with CO₂ concentrations. To control for the effects of land use change on streamflow, which may be a significant contributor to recent trends according to Piao et al. (2007), we employ only records from HCDN stations, which primarily represent minimally disturbed small watersheds.

2 Methods

2.1 Estimation of gridded streamflow

As constructed by Slack and Landwehr (1992), HCDN contains 1659 stream gauges, of which 1571 are in the coterminous United States (distribution shown in Fig. 1) and the remainder in Alaska, Hawai'i, Puerto Rico, and the Virgin Islands. Slack and Landwehr (1992) provide the available annual streamflows from HCDN gauges for the 1874–1988

Interactive Discussion

water years, which we updated from USGS through 2007. (USGS defines a water year as extending from October of the previous calendar year through September of the current year.) The average station has 55 years with complete daily streamflow records (allowing average annual streamflow to be calculated), with fewer station records available before the 1940s (Fig. 2).

Most of the streams in HCDN drain small watersheds (median drainage area: 740 square km; 10th–90th percentiles: 73–6800 square km). In interpolating measured annual streamflows onto a grid, we therefore treated them as point measurements on the much larger scale (8×10^6 square km) of the coterminous United States. We began by filling in missing years in the streamflow records from the sites that were available for a given year by regularized multiple linear regression (Schneider, 2001). This approach provides estimates of the uncertainty of the filled-in missing values, as well as estimates of the mean and covariance of the streamflow records that take into account information from multiple overlapping, correlated records. The streamflow records were normalized by subtracting the long-term mean from each series and dividing by its standard deviation. We then fit a two-parameter spatial covariance model (Handcock and Stein, 1993) to the streamflow series using a restricted maximum likelihood approach (Kitanidis, 1995). The correlation length of streamflow anomalies was found to be about 720 km (Fig. 3) and correlation decayed exponentially with distance, consistent with other analyses of the spatial correlation of streamflow (Lettenmaier et al., 1994). (For simplicity, we approximated the spatial correlation as homogenous and isotropic. This is not exactly the case; for example, correlelogram analysis showed that the correlation length was about 50% greater in the east than in the more mountainous west and about 40% greater in the east-west compared with the north-south direction.) Each stream record was assigned an error which includes the estimated uncertainty in the series mean and standard deviation, the estimated uncertainty of the filled-in values, and a constant error term intended to represent measurement error and sub-gridscale flow variability whose magnitude (0.06 standard deviations) was determined by restricted maximum likelihood. Finally, given the spatial covariance and error struc-

ture, each year's normalized streamflow at the gauge locations was interpolated, as in the standard geostatistical ("Kriging") approach (Cressie, 1993), to a 1° grid covering the coterminous United States. The gridded normalized streamflows were scaled by gridded mean and interannual standard deviation of streamflow per unit area from the analysis of Fekete et al. (2002) to produce estimates of actual streamflow per unit area (in mm/yr) for each water year.

2.2 Climate and greenhouse-gas concentration data

We sought to correlate streamflow anomalies to anomalies in local precipitation, large-scale temperature (not local temperature, because this can be strongly influenced by precipitation variations as well as influencing them) and atmospheric CO₂ concentration. We used gridded precipitation from the Global Historical Climatology Network (GHCN) Version 2, which is based on quality-controlled station observations over land processed to provide the best representation of long-term variability (Peterson and Vose, 1997, <http://www.ncdc.noaa.gov/oa/climate/research/ghcn/ghcngrid.html>). To get more accurate ratios of streamflow to precipitation, we downscaled the precipitation amounts from the 5° resolution of GHCN to the 1° resolution of our grid using climatological gridded precipitation from the University of East Anglia's Climate Research Unit (CRU; New et al., 1999, http://www.cru.uea.ac.uk/cru/data/hrg/cru_ts_2.10/), multiplying the GHCN time series for each grid cell by a scalar representing the ratio in the CRU climatology between the precipitation at 1° resolution and that at 5° resolution. Hemispheric and global monthly temperature anomalies were also taken from CRU (Jones and Moberg, 2003, <http://cdiac.esd.ornl.gov/trends/temp/jonescru/jones.html>). Yearly atmospheric CO₂ concentrations were estimated from direct measurements at Mauna Loa since the late 1950s and from ice core measurements beforehand (Enting et al., 1994).

3 Results

3.1 Streamflow trends and their correlation with precipitation

Figure 4 shows estimated annual streamflows for the coterminous United States, along with their uncertainty as estimated from the covariance and error structures of the HCDN records. This uncertainty was large in the first few decades, because there weren't enough records to accurately delineate patterns in annual streamflows (Fig. 2). We restricted our analysis of trends in streamflow to the period since 1920, when the streamflow gauge network appears to be dense enough to allow for accurate year-by-year reconstruction of large-scale streamflow patterns. (The estimated uncertainty shown in Fig. 4b does not include that introduced by scaling with the the analyzed mean and standard deviation from Fekete et al. (2002). This source of uncertainty, while difficult to quantify, would be expected to affect primarily our estimate of the absolute amount of streamflow and not its interannual variability.) We found periods of low streamflow in the 1930s and 1950s–1960s, and high streamflow in the 1970s and 1980s. A linear least-squares trendline of estimated streamflows over 1925–1994 supports Labat et al.'s (2004) finding of increasing streamflow in North America over this period: the regression coefficient is $+0.57 \pm 0.22$ mm/yr per year ($p=0.03$ for the null hypothesis of a regression coefficient of zero, using the F-test with the number of degrees of freedom adjusted for series autocorrelation (Bretherton et al., 1999)). However, the increase over this period mostly took place abruptly around 1970, rather than continuing steadily through recent decades. In fact, over the period 1994–2007, i.e. subsequent to that covered in Labat et al.'s analysis, streamflow shows a nonsignificant decreasing trend of -2.3 ± 2.2 mm/yr ($p=0.48$) (Fig. 5a).

As recognized by McCabe and Wolock (2002) for minimum and median annual streamflows, long-term trends in mean streamflow were well correlated with trends in precipitation, which also shows an abrupt increase around 1970 followed by essentially no trend since then (Fig. 5b). High-frequency interannual fluctuation in precipitation was also matched by fluctuations in streamflow. In fact, as Fig. 6 shows, most of

Interactive Discussion

the streamflow variability could be explained by a linear dependence on current-year precipitation ($R^2=0.70$).

Our gridded streamflow product permits us to compare not only trends in streamflow and precipitation averaged over the coterminous US but also spatial patterns in streamflow with spatial patterns in precipitation at comparable effective resolution over particular time periods. As an example, Fig. 7 shows maps of interdecadal change in streamflow and precipitation. Between 1945–1965 and 1970–1990, precipitation increased over most of the US, with a particularly pronounced increase in the northeast, but decreased over Florida and the northwest. Between 1970–1990 and 1995–2007 precipitation increased in the upper Great Plains and northern California but decreased in the Rocky Mountain region and in the southeast. In both cases, streamflow shows quite similar trends.

Annual streamflow correlated well with annual precipitation throughout most of the coterminous US (Fig. 8). This dependence was weakest in the Great Plains, where precipitation is concentrated in the summer and only a small fraction runs off, so that the timing of rainfall and the antecedent soil moisture status may be relatively more important to determining streamflow than the annual total, and strongest in the moist east and the Pacific coast.

3.2 Impact of global warming and atmospheric CO₂ on streamflow

While the major direct cause of interannual variability in streamflow is variability in precipitation, changing temperature and CO₂ level might also be expected to affect streamflow, the former through influencing evaporation rates, and the latter by affecting plant water use efficiency. In an attempt to isolate the impact on streamflow of global warming and of increasing ambient CO₂ levels, we performed multiple linear regression of streamflow against annual precipitation, temperature, and CO₂ level. We caution that because global temperature is well correlated with CO₂ levels, linear regression has limited ability to distinguish the separate effects of these two factors. For the coterminous US we found opposing impacts of temperature and CO₂ in the expected

Interactive Discussion

directions, with warming reducing streamflow while higher CO₂ increases streamflow (Table 1).

Since (greenhouse) warming and rising CO₂ have been well correlated and are likely to remain so in coming decades, a possibly more important question is the net effect of the combination of high CO₂ and warming. Regression of streamflow against precipitation and CO₂ alone showed that the overall effect of greenhouse warming has probably been to reduce streamflow, though the association is not significant for the coterminous US as a whole (Table 1).

The dependence of streamflow on global temperature and CO₂ level varied by region (Fig. 9b). CO₂ seems relatively most influential in increasing streamflow in the Great Plains, while in the east, with its wetter conditions, and in the far west, with its concentration of winter precipitation, the positive impact of CO₂ on streamflow is less strong than the negative impact of warming. Dividing the coterminous United States based on the percentage of precipitation that falls during the warm months shows this division clearly (Fig. 9a; Table 1).

4 Discussion

4.1 Is greenhouse warming causing the observed increase in streamflow?

Figure 10 shows coterminous United States precipitation versus global temperature for each year in 1901–2005. While the two time series show a nominally significant positive correlation of +0.35 ($p < 0.001$) because the higher precipitation after 1970 corresponds to warmer global temperatures, segmenting the time series at 1970 shows that the correlation is mostly due to the abrupt jump in precipitation around 1970 rather than a more consistent trend (correlation for 1901–1970 +0.19, for 1970–2005 +0.09, both with $p > 0.05$). This jump in precipitation has been tentatively linked with changing circulation patterns in the Atlantic Ocean, possibly reinforced by increasing aerosol emissions in the 1960s (Baines and Folland, 2007). In any case, there is no clear

Interactive Discussion

response of coterminous United States precipitation to global temperature in the observational record.

Absent a direct effect of greenhouse warming on coterminous US precipitation, most of the US shows a negative impact of greenhouse warming on streamflow, which could be explained through the increased evaporation due to global warming more than offsetting the increased plant water use efficiency due to higher CO₂ concentrations. While separating the temperature from the CO₂ impacts based on observational data is uncertain because both these factors are increasing over time in a similar manner, our multiple regression of streamflow against temperature and CO₂ level provides some support for the contention of [Gedney et al. \(2006\)](#) that a direct CO₂ impact on streamflow is detectable. Our inference that total evaporation nevertheless is increasing with warming is consistent with in situ measurements of evaporation ([Golubev et al., 2001](#)).

We found that the apparent CO₂ impact on streamflow is strongest in parts of the United States where summer precipitation dominates. This pattern agrees with the expectation that the impact of increased plant water use efficiency on streamflow should be largest where precipitation is concentrated during the growing season and therefore is efficiently intercepted by plants, as opposed to where much precipitation occurs in winter so that growing-season transpiration has a relatively smaller impact on streamflow ([Wigley et al., 1984](#)).

4.2 What do observed trends suggest about future moisture regimes?

Our results show that fitting a linear trend to streamflow (or precipitation) data can be highly misleading for understanding decadal variability and for extending observed patterns into the future. While coterminous United States streamflow and precipitation have indeed increased in recent decades, this increase took place abruptly over a few years around 1970, rather than as part of a steady “acceleration of the hydrologic cycle” in step with greenhouse gas concentrations or global warming. Thus, there is no clear reason to expect continued increases in streamflow with greater warming. If precipitation follows its post-1970 trend and fails to increase with additional warming,

Interactive Discussion

we should expect streamflow to continue to decrease over most of the United States, as it has since the early 1990s, due to intensified evaporation (incompletely offset by the physiological impact of CO₂ on plants). Indeed, increasing drought over the United States since the early 1990s is proposed to have caused a reduction in the summer drawdown of atmospheric CO₂ observed at Mauna Loa, as water stress reduced plant carbon uptake during the growing season (Buermann et al., 2007). The global trend since the 1970s has also been toward more frequent drought occurrence (Dai et al., 2004). Extending our work through objective interpolation of streamflow trends in other regions where many long records are available would help give a clearer picture of how decadal hydrologic variability and the effects of greenhouse warming on the water cycle vary between continents and biomes.

Considering only annual mean streamflow and precipitation may not be sufficient for understanding how water stress and water resource availability have changed and may change. For example, part of the increase in streamflow observed in the Great Plains that our regression analysis attributed to increasing atmospheric CO₂ could instead be due to reduced interannual precipitation variability (Garbrecht and Rossel, 2002) or to a disproportionate increase in cold-season (as compared with summer) precipitation (Garbrecht et al., 2004). Our interpolation technique could equally well be applied to seasonal or monthly as well as annual mean streamflow, and thus distinguish the hydrologic impacts of these as well as other seasonally specific factors as advances in spring snowmelt and changing vegetation phenology. It is also important to examine how changes in precipitation intensity (Groisman et al., 2001) might also affect streamflow and other aspects of the water cycle. Comparing trends in gridded streamflow from a larger gauge network with the trend estimated using HCDN could independently validate model assessments of the impact on streamflow of human land use and water diversion, whereas in this study we chose to obtain trend estimates that exclude land use impacts insofar as possible. Finally, combining gridded streamflow and precipitation with remotely sensed water storage would give a fuller picture of how climate variability is affecting stored soil water and groundwater.

5 Conclusions

We developed maps of annual streamflow anomalies over the coterminous United States. We find that streamflow increased around 1970 in concert with an increase in precipitation, but has not increased since then. Our analysis supports net drying as a result of greenhouse warming, with some evidence for the opposing effects of temperature and CO₂ increase. This suggests a high risk of reduced water supplies and increased plant water stress with continued warming in coming decades.

US streamflow trends

N. Y. Krakauer and
I. Fung

Table 1. Streamflow variability by precipitation seasonality and for the entire coterminous US

	Entire coterminous US	<35% summer rain	35–65% summer rain	>65% summer rain
Area (10^6 km^2)	7.85	0.68	3.93	3.19
Mean precipitation (mm/yr)	736	748	837	599
Mean streamflow (mm/yr)	151	311	211	39
Streamflow:precipitation regression coefficient ^a	0.54 ± 0.04	0.49 ± 0.02	0.69 ± 0.04	0.31 ± 0.03
Intercept (mm/yr) ^b	463	126	542	475
Streamflow:CO ₂ regression coefficient ^c	$+37 \pm 18$	$+28 \pm 21$	$+34 \pm 22$	$+38 \pm 18$
Streamflow:temperature regression coefficient ^c	-56 ± 18	-70 ± 20	-67 ± 21	-16 ± 12
Streamflow:CO ₂ alone regression coefficient ^d	-13 ± 10	-37 ± 11	-27 ± 12	$+12 \pm 8$

^a For a regression of streamflow against precipitation alone (coefficient is unitless, mm/yr per mm/yr).

^b Precipitation at zero streamflow (a measure of “baseline” plant transpiration and evaporative demand).

^c For a regression of streamflow against precipitation, temperature, and CO₂ level (coefficients expressed as mm/yr streamflow per 100 ppm CO₂ and mm/yr streamflow per K, respectively).

^d For a regression of streamflow against precipitation and CO₂ level (coefficient expressed as mm/yr streamflow per 100 ppm CO₂).

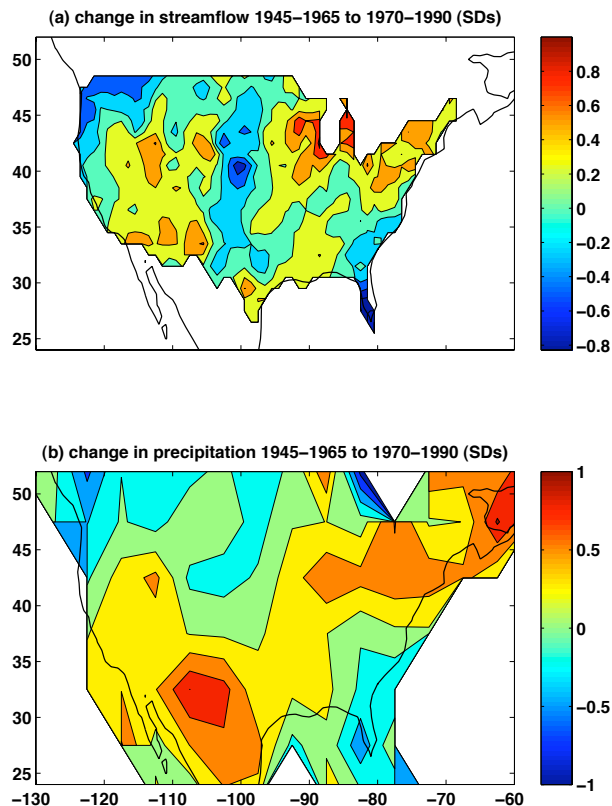

Fig. 7. (a–b) Change in average streamflow and precipitation between 1945–1965 and 1970–1990 (later period minus earlier period). **(c–d)** Same, but between 1970–1990 and 1995–2007 (1995–2005 for precipitation). Changes have been normalized by the interannual standard deviation at each point so that changes in wet and dry regions have comparable magnitude.

Interactive Discussion

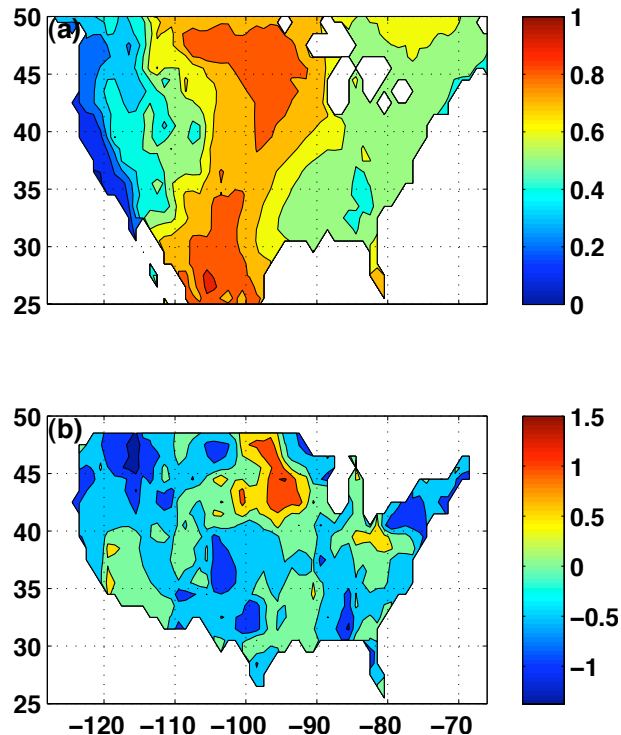

Fig. 9. (a) Summer dominance of precipitation, defined as the fraction of climatological annual precipitation that falls during warmer than average months of the year. **(b)** Apparent response of streamflow to greenhouse warming: the regression coefficient of CO_2 level on annual streamflow in a multiple regression of streamflow against precipitation and CO_2 (so that the effect of global warming is implicitly included in the CO_2 term). Units are streamflow standard deviations per 100 ppm CO_2 . The standard error of the regression coefficient is about 0.3 SD/100 ppm CO_2 .

I. Fung

Fig. 10. Annual global temperature and coterminous US precipitation, 1901–2005. Blue squares are years from 1901–1970, red circles are years from 1971–2005. The solid line is the least-squares regression line for the entire period, while the blue and red dashed lines are regression lines for the periods 1901–1970 and 1970–2005, respectively. While over the whole period precipitation is significantly, if weakly, correlated with temperature ($R^2=0.12$), the correlation vanishes after 1970.
